43 **Abstract**

44 Retrograde transport of NF- κ B from the synapse to the nucleus in neurons is mediated by
45 the dynein/dynactin motor complex and can be triggered by synaptic activation. The calibre
46 of axons is highly variable ranging down to 100 nm, aggravating the investigation of transport
47 processes in neurites of living neurons using conventional light microscopy. In this study we
48 quantified for the first time the transport of the NF- κ B subunit p65 using high-density single-
49 particle tracking in combination with photoactivatable fluorescent proteins in living mouse
50 hippocampal neurons. We detected an increase of the mean diffusion coefficient (D_{mean}) in
51 neurites from $0.12 \pm 0.05 \mu\text{m}^2/\text{s}$ to $0.61 \pm 0.03 \mu\text{m}^2/\text{s}$ after stimulation with glutamate. We
52 further observed that the relative **amount** of retrogradely transported p65 **molecules** is
53 increased after stimulation. Glutamate treatment resulted in an increase of the mean
54 retrograde velocity from 10.9 ± 1.9 to $15 \pm 4.9 \mu\text{m}/\text{s}$, whereas a velocity increase from 9 ± 1.3
55 to $14 \pm 3 \mu\text{m}/\text{s}$ was observed for anterogradely transported p65. This study demonstrates for
56 the first time that glutamate stimulation leads to an increased mobility of single NF- κ B p65
57 molecules in neurites of living hippocampal neurons.

59

60 Introduction

61 The inducible transcription factor NF- κ B is involved in crucial brain functions including
62 learning and memory formation (1-7). The most abundant NF- κ B heterodimer detected within
63 the central nervous system (CNS) is composed of p65 and p50 (3, 8, 9). We and others have
64 shown that NF- κ B is localized in the synapse, can be activated by glutamate at synaptic
65 sites, and is transported back to the nucleus after its activation (3, 10-15).

66 Axons and dendrites represent specialised neuronal cytoplasmic extensions, where
67 movement by random diffusion alone would not permit efficient and directed delivery of
68 proteins over long distances (16, 17). However, signals generated at synapses must be
69 transported back to the nucleus to regulate gene expression (reviewed in (17)).

70 Anterograde (away from nucleus) and retrograde (towards the nucleus) transport are crucial
71 for the physiological function of neurons and are mediated by motor proteins including dynein
72 and kinesins (18, 19). Due to their polarised nature and the relatively long distance between
73 the nucleus and the periphery, neurons are highly dependent on intact active transport
74 machinery (reviewed in (20)). Consequently, defects in axonal transport are involved in
75 development of several neurodegenerative diseases, including Alzheimer's, Parkinson's, and
76 Huntington's disease (21). We and others have previously demonstrated neuronal NF- κ B is
77 actively transported towards the nucleus by the minus end-directed motor protein dynein
78 ((11, 22, 23), Fig. 1). In contrast, diffusion seems to be sufficient for its retrograde transport in
79 non-neuronal cells (24). However, the exact biophysical parameters such as diffusion
80 coefficients and velocity of retrogradely transported NF- κ B were unknown.

82

83

84

85

Single-particle tracking (SPT) of fluorophore-labelled receptors in the plasma membrane of a live cell provides valuable information on dynamics and interactions (25). In combination with photoswitchable fluorophores (26), SPT allows the observation a large number of molecules by stochastically activating only a small subset of fluorophores at a given time and tracking them until photobleaching. This cycle of photoactivation, tracking and photobleaching is repeated many (often a few thousand) times. Profiting from the pool of labelled biomolecules in a sample, a large number of single-molecule trajectories are recorded. Single-particle tracking with photoactivated-localization microscopy (SPT-PALM, (27)) allows longer observation times, provides better statistics (28, 29) and allows high-density mapping of molecular movements (30).

In order to study the dynamics of retrogradely transported NF- κ B in neurons at the single-molecule level, we applied SPT-PALM (27, 31) and used the fluorescent protein tandem-Eos-FP (tdEos) as a reporter (27, 28). tdEos is photoconverted from a green-fluorescent to an orange-fluorescent species by irradiation with 405 nm light (32). Following this procedure, a small stochastic subset of the tdEos is transferred into the active (orange-fluorescent) state and tracked as single molecules. In the present study, we used this technique to visualise p65-tdEos (NF- κ B subunit fused to tdEos) with a localization precision of 26 nm (Fig. 2A).

103

We investigated the glutamate-induced transport of NF- κ B p65 in living hippocampal neurons with single-molecule resolution and determined the respective diffusion coefficients. Finally, we demonstrated that synaptic activity leads to an increased mobility of retrogradely and anterogradely transported neuronal NF- κ B p65.

108 **Results and Discussion**

109

Hippocampal neurons transfected with p65-tdEos were identified by widefield imaging detecting the green fluorescence signal from unconverted p65-tdEos. After identification of the soma (containing the nucleus), neurites of transfected cells were irradiated with low intensities of UV light and single p65-tdEos molecules were tracked by their orange

114 fluorescence. Several thousands of trajectories per cell were recorded and used to generate
115 a trajectory map (Fig. 2B).

116 Next, we compared the mobility of NF- κ B p65 in unstimulated and glutamate-treated
117 neurons. We observed that glutamate treatment led to an increased mobility of p65-tdEos
118 particles compared to the baseline control (Fig. 2B). This increase in mobility is in general
119 accordance with the reports on rapid retrograde transport of NF- κ B in neurons after
120 glutamate treatment (11, 22).

121 We then calculated the mean diffusion coefficient (D_{mean}) of p65-tdEos molecules from the
122 SPT-PALM data (Fig. 3). In the absence of stimulation (baseline) p65-tdEos molecules
123 showed a D_{mean} of $0.12 \pm 0.05 \mu\text{m}^2/\text{s}$ (Fig. 3A). Stimulation with glutamate resulted in a higher
124 occurrence of fast molecules (D_{mean} of $0.61 \pm 0.03 \mu\text{m}^2/\text{s}$) compared to unstimulated controls
125 (Fig. 3A-B) and narrowed the distribution of single-molecule diffusion coefficients (Fig. 3A-B).
126 Notably, the D_{mean} measured for p65-tdEos without stimulation is in a similar range than
127 diffusion coefficient reported for the cytoplasmic HIV Gag-Eos fusion ($0.11 \pm 0.08 \mu\text{m}^2/\text{s}$)
128 (27). After stimulation with glutamate, D_{mean} of p65-tdEos is similar to mobile fraction of
129 membrane residing α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors
130 with a diffusion coefficient of $>0.5 \mu\text{m}^2/\text{s}$ (33). We further followed how the mobility of p65-
131 tdEos developed with time and found that the glutamate-dependent increase in D_{mean} persists
132 for at least 400 s (Fig. 3D).

133 Next, we determined the extent to which glutamate affects the immobile fraction as well as
134 retrogradely and anterogradely transported p65-tdEos particles. In glutamate-stimulated
135 neurons, we recorded a lower occurrence of immobile molecules in neurites that was
136 accompanied by significant increase in retrogradely transported p65-tdEos (Fig. 4A). Further,
137 although not significant, a slight increase of anterogradely transported molecules was
138 measured. Finally, we determined the velocities of single transported p65-tdEos particles.
139 Although glutamate treatment resulted in heterogeneous velocity distribution for both
140 retrograde and anterograde transport, a significantly increased mean velocity was assessed

in both directions (Fig. 4B). Specifically, glutamate treatment resulted in an increase of the mean retrograde velocity from 10.9 ± 1.9 to 15 ± 4.9 $\mu\text{m/s}$, whereas a mean velocity increase from 9 ± 1.3 to 14 ± 3 $\mu\text{m/s}$ was observed for the anterograde transport. Notably, the mean velocities calculated for p65-tdEos are in the same range reported for the transport of NGF in neurites of rat sympathetic neurons ($\sim 3\text{-}6$ $\mu\text{m/s}$) as measured in compartmented cultures after applying radioactive ^{125}I -NGF (34). In neuronal cells, the transport of mitochondria is accomplished by microtubule-based motors (kinesins and dynein) with velocities ranging from $\sim 5\text{-}30$ $\mu\text{m/s}$ (35). Moreover, flagellar dyneins achieve a velocity of up to 19 $\mu\text{m/s}$ (reviewed in (36) and (37)), which is again in general accordance with the mean velocity of 15 $\mu\text{m/s}$ for p65-tdEos after glutamate treatment (this study).

In summary, we report that glutamate stimulation promotes an increase in mobility of the NF- κB subunit p65 in living hippocampal neurons. Exposure of neurons to glutamate leads to an increased mean diffusion coefficient of p65-tdEos and an increase in the velocity of both- retrogradely and anterogradely transported NF- κB p65 in neurites.

Methods

Astrocyte cultures

Mouse astrocytes were prepared from the cortex of postnatal day 1 (P1) BL6 mice, after treatment with 1x Trypsin/EDTA (PAA, Pasching, Austria). The astrocytes were washed with pre-warmed DMEM (37°C, PAA) and transferred to DMEM containing 2 mM L-glutamine, 100 U/ml penicillin and streptomycin and 10 % fetal bovine serum (PAA). Cells were cultured in a humidified incubator at 95% air, 5% CO_2 . 1 day prior to hippocampi preparation, astrocyte growth was blocked with 10 $\mu\text{g/ml}$ mitomycin (Sigma-Aldrich, Deisenhofen, Germany) for 1.5 h followed by washing with DMEM (PAA) and cultivation in DMEM supplemented with 2mM L-glutamine, 100U/ml penicillin and streptomycin and 10% fetal

bovine serum (PAA). Prior to preparation of the hippocampi, the astrocytes were transferred to pre-warmed Neurobasal medium (Invitrogen, Darmstadt, Germany) containing B27 supplement (Invitrogen), 2 mM L-glutamine (PAA), 100 U/ml penicillin (PAA) and 100 U/ml streptomycin (PAA).

Hippocampal neuron cultures

Primary cultures of mouse hippocampal neurons were prepared from the hippocampi of E18-E19 BL6 mouse embryos, after treatment with 1x Trypsin/ETDA (15 min, 37°C; (0.05 % / 0.002 % in PBS), PAA). The hippocampi were washed with pre-warmed DMEM (37° C) containing 10 % FCS, to stop trypsin activity and transferred to pre-warmed DMEM (PAA) supplemented with 2 mM L-glutamine, 100 U/ml penicillin (PAA) and 100 U/ml streptomycin (PAA) and 10 % foetal bovine serum (PAA). The cells were dissociated under these conditions using a fire-polished Pasteur pipette followed by seeding on poly-D-Lysine (Sigma-Aldrich) coated coverslips at a density of 50,000 cells/18 mm. The cultures were maintained in a humidified incubator at 5 % CO₂ for 60 min to allow adherence. Subsequently, neurons on coverslips were placed on top astrocyte cultures and further cultivated at 5 % CO₂.

Anaesthesia of neuronal activity for baseline of nuclear NF-κB and glutamate treatment

24 h prior to experimentation, hippocampal neuron cultures were treated with 40 μM 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX, Sigma-Aldrich), 100 μM 2-amino-5-phosphonopentanoic acid (APV, Sigma-Aldrich) and 10 μM nimodipine (Sigma-Aldrich) to establish a stable and low baseline of nuclear NF-κB as described before (22, 23). Afterwards, neurons were washed and exposed to 300 μM glutamate or PBS (Sigma-Aldrich) for 5 min in the absence of the inhibitors at 37°C. Subsequently, the stimulus was washed out and cultures were incubated with complete medium at 37°C for 90 min.

194 *Immunocytochemical staining*

195 Immunocytochemistry was performed as described in (22). Briefly, neurons were fixed in
 196 3.7% PFA for 60 min at 4°C, permeabilised with 0.1% Triton X-100 in PBS followed by
 197 incubation with rabbit polyclonal anti- NF-κB p65 antibody (sc-109; Santa Cruz
 198 Biotechnology, Inc., Santa Cruz, CA) diluted 1:100. Neurons were washed and incubated
 199 with goat anti-rabbit antibody coupled to Cy3 (1:300, Jackson Immuno Research
 200 Laboratories, distributed by Dianova, Hamburg, Germany). Nuclear staining was performed
 201 with SYTOX (1:10000, Molecular Probes, Göttingen, Germany).

202

203 *SPT-PALM imaging, single molecule segmentation and tracking*

204 The tdEos fusion to p65 was achieved by subcloning of p65 (38) into pcDNA3-Flag1-td-
 205 EosFP (MoBiTec). Hippocampal neurons were transiently transfected with p65-tdEos
 206 overnight using Effectene (Qiagen) according to the manufacturer's guidelines. Cells were
 207 imaged at 37°C in an open chamber (Ludin Chamber, Life Imaging Services) mounted on an
 208 inverted motorized microscope (Nikon Ti-E, Nikon, Japan) equipped with a 100x1.45NA PL-
 209 APO (Nikon) objective and a perfect focus system. To identify transfected cells, the
 210 fluorescence from the non-photoconverted tdEos was recorded using excitation light at 488
 211 nm and a GFP filter cube (ET470/40, T495LPXR, ET525/50, Chroma, USA). Cells
 212 expressing the tdEos constructs were selected for SPT-PALM imaging. Irradiation at 405 nm
 213 using a diode laser (Omicron, USA) at low intensities lead to photoconversion of tdEos which
 214 was read-out with a 561 nm laser (Cobolt, Sweden). The respective irradiation intensities
 215 were adjusted to keep the number of the stochastically activated molecules at low single
 216 molecule density, and leave single molecules fluorescent during multiple frames before
 217 bleaching. The fluorescence was collected by the combination of a dichroic and emission
 218 filters (D101-R561 and F39-617 respectively, Chroma, USA) and a sensitive EMCCD camera
 219 (Evolve, Photometric, USA). The acquisition was steered by Metamorph software (Molecular
 220 Devices) in streaming mode at 50 frames per second (20 ms exposure time). Recording
 221 times for single cells varied from 5 min to 30 min. Single molecule fluorescent spots were

localized in each image frame and tracked over time using a combination of wavelet segmentation and simulated annealing algorithms (39-41). The localization accuracy of the SPT-PALM microscope under our experimental conditions was quantified by using fixed samples expressing tdEos. Localization precision was determined to 26 nm using a nearest neighbour approach, according to (42). The software package used to visualize and derive quantitative data on protein localization and dynamics was custom written for Metamorph (Visitron Systems GmbH, Puchheim, Germany).

An average of > 500 trajectories per cell with a minimum trajectory length of 8 frames was obtained and analysed. For these trajectories, the mean square displacement (MSD) was calculated according to the formula $MSD = \Delta x^2 + \Delta y^2$. The diffusion coefficient was extracted by approximating the first 4 points of a plot of D_{mean} versus time using the relationship of $MSD = 4Dt$. The mean diffusion coefficient (D_{mean}) was calculated as an average from all single-molecule diffusion. Kymographs were used to define immobile, retrogradely and anterogradely moving particles (according to the position of the soma and the neurites). For exemplary MSD-analysis see Fig. 2C.

Statistical analysis

Statistical significance was determined by ANOVA using Bonferroni post-test, or if appropriate using two-tailed Student's t-tests using GraphPad's Prim Software. P values < 0.05 were considered significant.

Figure legends

Figure 1. Synaptic activity promotes dynein-dependent retrograde transport of NF- κ B to the nucleus. **A.** Hippocampal neurons were treated with 300 μ M glutamate for 5 min. Cells were fixed (90 min after glutamate exposure) and visualised by SYTOX nuclear staining (green) and anti NF- κ B p65 immunofluorescence (magenta) to monitor neuronal transport of NF- κ B (data from (22), CC BY license). Note that glutamate promotes nuclear translocation of NF- κ B subunit p65. **B.** Schematic presentation of retrograde transport of NF- κ B in neurons. After stimulation of the neuron with an activator such as glutamate, upstream kinases induce phosphorylation of the inhibitory protein I κ B stimulating its proteasomal degradation. This allows the binding of p65/p50 heterodimers to the dynein/dynactin motor proteins. After the assembly of the complex and its retrograde movement along the microtubule network, NF- κ B translocates into the nucleus without disruption of the complex and induces transcription of specific target genes.

Figure 2. SPT-PALM imaging of NF- κ B p65 in hippocampal neurons. **A.** The NF- κ B p65 subunit was fused to the photoactivatable fluorescent protein tandem-Eos-FP (tdEos) that can be photoconverted by irradiation with UV light. Transfected neurons were identified in widefield fluorescence mode by detecting the green fluorescence signal of the tdEos in p65-tdEos. A small stochastic subset of the p65-tdEos was photoconverted from a green-fluorescent to an orange-fluorescent species and tracked as single molecules. Localization precision for tdEos was determined to 26 nm using a nearest neighbour approach, as described in (42). **B.** Map of single particle trajectories (middle and lower panel) revealed highly increased mobility of p65-tdEos in neurites after glutamate stimulation compared to controls. Representative data set from a single cell for both conditions is shown. **C.** Exemplary MSD plots from single-molecule trajectories of untreated (blue) and

glutamate-treated (red) p65-tdEos. The first four MSD values were considered for extracting the diffusion coefficient.

Figure 3. A-B. Effect of glutamate on the distribution of diffusion coefficients of NF- κ B in hippocampal neurons. Note that glutamate treatment narrows the distribution of single-molecule diffusion coefficients compared to the control. **C.** Average diffusion coefficient D_{mean} of p65-tdEos under baseline conditions and after treatment with glutamate monitored over time (a representative data set from a single cell each is shown). Glutamate treatment leads to significantly increased D_{mean} . Without stimulation p65 molecules showed D_{mean} of $0.12 \pm 0.05 \mu\text{m}^2/\text{s}$. Stimulation with glutamate resulted in a strongly increased occurrence of fast particles and D_{mean} of p65 to $0.61 \pm 0.03 \mu\text{m}^2/\text{s}$. **D.** D_{mean} of p65-tdEos under control conditions and after treatment with glutamate monitored over time (a representative data set from a single cell each is shown). Error bars: SEM

Figure 4. A. Effect of glutamate on velocity of retrogradely and anterogradely transported p65-tdEos particles. Single-molecule data was used to calculate the occurrence of immobile and retro- and anterogradely transported p65. Treatment of hippocampal neurons with glutamate resulted in significantly decreased amount of immobile particles and strongly increased retrograde transport. **B.** Glutamate treatment increases the mean velocity of retrogradely and anterogradely transported p65-tdEos.
