ABSTRACT

8 Previous studies have highlighted an important organising influence of the
9 seasonal Southern Hemisphere stratospheric vortex breakdown on the large-
10 scale stratospheric and tropospheric circulation. The present study extends
11 this work by considering the statistical predictability of the stratospheric vor-
12 tex breakdown event, using re-analysis data. Perturbations to the winter
13 stratospheric vortex are shown to persist into austral spring, and to lead to
14 a shift in the statistics of the breakdown event during austral summer. This
15 is interpreted as evidence for the potential for seasonal predictability of the
16 vortex breakdown event in the stratosphere. Coupled variability between the
17 stratosphere and troposphere is then considered. The semi-annual oscillation
18 of the tropospheric mid-latitude jet is discussed and evidence for a connec-
19 tion between this behaviour and variations in the stratosphere is presented.
20 Based on this connection, an argument is made for the concomitant poten-
21 tial for seasonal predictability in the troposphere, assuming knowledge of the
22 stratospheric initial state. Combining these various results, a non-stationary,
23 regime-based perspective of large-scale extra-tropical Southern Hemisphere
24 circulation variability between late winter and summer is proposed. The im-
25 plications of this perspective for some previous studies involving Annular
26 Modes of the circulation are discussed. In particular, the long Annular Mode
27 timescales during austral spring and summer should not be interpreted as an
28 increased persistence of perturbations to some slowly varying seasonal cycle,
29 but instead reflect a phase shift of the seasonal cycle induced by stratospheric
30 variability.

31 **1. Introduction**

32 Seasonal climate prediction is distinct to conventional weather forecasting in that it does not
33 attempt to forecast the day-to-day evolution of weather. Instead it attempts to provide estimates
34 of time-mean statistics, typically several months in advance (Palmer and Anderson 1994). The
35 theoretical basis for such extended-range prediction is attributed to two fundamental constraints
36 on the evolution of the atmosphere: the surface boundary conditions and the atmospheric initial
37 conditions. Traditionally it has been the surface boundary conditions that have been the primary
38 focus of attention. In particular, the phenomenon of El Niño-Southern Oscillation (ENSO) has
39 formed the key paradigm for the design and implementation of many modern seasonal forecast
40 systems (National Research Council 2010; Butler et al. 2016). More recently, evidence has been
41 offered for the importance of the atmospheric initial conditions (Stockdale et al. 2015), with the
42 role of the stratospheric polar vortex receiving much attention. Much of this work has focused on
43 the Northern Hemisphere (NH) and in particular on the influence of sudden stratospheric warmings
44 (SSW) on the tropospheric circulation (Sigmond et al. 2013). However, there also exists a related
45 body of work for the Southern Hemisphere (SH; Son et al. 2013; Seviour et al. 2014). SSW events
46 are exceedingly rare in the SH (Roscoe et al. 2005) and so the source of this apparent skill requires
47 a somewhat different explanation to that proposed for the NH.

48 The seasonal evolution of the SH stratospheric polar vortex (SSPV) exhibits several distinct fea-
49 tures compared to its NH counterpart. In particular, the SSPV undergoes an annual downward shift
50 in its location relative to its midwinter position (Hartmann et al. 1984). The ‘shift-down’ behaviour
51 of the SSPV (Hio and Yoden 2005) typically proceeds from mid-late August and culminates in the
52 vortex breakdown event sometime between mid-November and mid-January. The seasonal evo-
53 lution of the SH tropospheric mid-latitude jet/eddy-driven jet (EDJ) also exhibits several distinct

54 features compared to its NH counterpart. In particular, the EDJ undergoes a semi-annual oscillation (SAO) in latitude with the strongest winds closest to the pole in autumn and spring (van Loon
55 1967). The interannual variability of both of these components of the large-scale SH circulation
56 was previously investigated by Kuroda and Kodera (1998), who documented an apparently coupled relationship between the SSPV and EDJ from midwinter until the vortex breakdown event in
57 summer. These authors noted that during this period the variability of the coupled system appeared
58 to be an ‘interannual phenomenon with a well-defined intraseasonal structure’. This work was further extended by Hio and Yoden (2005), who noted two distinct configurations for the late winter
59 SSPV and who referred to a ‘seasonal march’ of the coupled variability. These authors conditioned
60 their analysis on the late winter configuration of the SSPV and presented evidence that between
61 August and December, the time-mean statistics of the large-scale extra-tropical tropospheric and
62 stratospheric circulations were a function of this late winter configuration. A potential link between the stratospheric quasi-biennial oscillation (QBO) and the configuration of the winter SSPV
63 was also investigated by both Kuroda and Kodera (1998) and Hio and Yoden (2005).

64 More recently, evidence has been presented of an equatorward transition of the EDJ in association with the stratospheric vortex breakdown event (Byrne et al. 2017), with the timing of this
65 transition representing a leading-order influence on large-scale tropospheric circulation variability
66 during this time of year. Figure 1 illustrates the extent of this influence - 500hPa geopotential
67 height anomalies averaged over the summer months are correlated against the date of the stratospheric vortex breakdown for each year during the satellite era. The significant correlation values
68 at high-latitudes are indicative of the impact of year-to-year variability in the timing of the vortex breakdown event in the stratosphere on tropospheric circulation anomalies (see Tripathi et al.
69 (2015) for a review of some of the potential dynamical mechanisms involved in this coupling). A
70 natural question that emerges from this work is to ask how predictable (in a seasonal forecasting
71
72
73
74
75
76
77

78 sense) the timing of this event might be, and how it relates to the earlier work of Kuroda and
79 Kodera (1998) and Hio and Yoden (2005). It is also of interest to try to understand how these
80 results might relate to the ‘Annular Modes’ of the circulation, which in recent years have become
81 the de-facto choice for diagnosing stratosphere-troposphere coupling and the associated prospects
82 for seasonal forecasting (e.g., Kidston et al. 2015, and references therein). The Annular Modes
83 represent the dominant patterns of extratropical circulation variability in both hemispheres and
84 correspond to a latitudinal shift of the EDJ in the troposphere and to a change in strength of the
85 stratospheric polar vortex in the stratosphere (Thompson and Wallace 2000).

86 The present paper is an attempt at investigating these questions, using re-analysis data. It be-
87 gins by exploring the extent to which the date of the stratospheric vortex breakdown is statisti-
88 cally predictable. This is done by relating interannual variations in the timing of the breakdown
89 event to persistent variations of the SSPV in the preceding winter and spring. Coupled variability
90 between the stratosphere and troposphere is then considered, and an argument is made for the
91 concomitant potential for skilful seasonal forecasting in the troposphere. Based on these results
92 a non-stationary, regime-based perspective of large-scale extra-tropical SH circulation variability
93 between late winter and summer is proposed. The paper concludes with a summary of results and
94 a discussion of possible future work.

95 **2. Data and Methods**

96 The basic data input for our study is four-times daily zonal wind and geopotential data from
97 the ERA-Interim re-analysis dataset for the period Mar 1 1979 to Feb 28 2017 (Dee et al. 2011).
98 This period encompasses 38 years in the SH in total. Data was available on an N128 Gaussian
99 grid and on 37 pressure levels (1000 - 1 hPa). Before analysing the data we first processed it by
100 forming a daily and zonal average of the data. This processed data formed the input for all of our

subsequent analysis. We define a climatology of our data as the long-term daily average that is subsequently smoothed by retaining the first six Fourier harmonics (Black and McDaniel 2007). We define a daily jet latitude index by vertically averaging zonal-mean daily-mean zonal wind data between 1000 and 250hPa, and subsequently computing the latitude of the maximum value of this average between 0 and 90 S (Byrne et al. 2017). We identify the date of the stratospheric vortex breakdown as the final time that the zonal-mean daily-mean zonal wind at 60 S drops below 10 m s^{-1} ; we apply this criterion to running 5-day averages at 50hPa (Black and McDaniel 2007). We use 60 S as the boundary for our polar-cap average. We define the phase of the QBO using the sign of July monthly-mean zonal-mean zonal wind at 20hPa averaged between 5 N and 5 S (Anstey and Shepherd 2014). We define our SAO index as the difference between monthly-mean zonally-averaged sea-level pressure at 50 S and 65 S (Bracegirdle 2011). We define our Annular Mode index for each pressure level of our data in a similar manner to Baldwin and Thompson (2009). First we compute daily anomaly data of zonal-mean daily-mean geopotential height by removing a daily climatology. Next we perform an empirical orthogonal function (EOF) analysis between 20 and 90 S and at each individual level; we weight our data to account for the decrease in area toward the pole (North et al. 1982). Finally we define our Annular Mode index as the normalised principal component time series that results from our EOF analysis. For our Annular Mode composite analysis we consider years with the 13 largest positive and 13 largest negative values in our Annular Mode index at 30hPa. These represent approximately the upper and lower terciles of our data. We composite about an onset date which is defined as the day when anomalies in the Annular Mode index at 30hPa cross the two-standard deviation threshold for the final time prior to the peak of the event (Thompson et al. 2005).

3. Stratospheric Circulation Variability

a. Climatology and Interannual Variability

The shift-down of the SSPV typically proceeds from mid-late August (Hartmann et al. 1984). Long-term monthly average plots of zonal-mean zonal wind ($[u]$) are plotted from August in Figure 2. Clear evidence of the downward progression and a general weakening of the winds can be seen in this figure.¹ There is also a suggestion of something of a merger with the tropospheric EDJ and a tilting of the SSPV from late September onwards. The downward progression of the SSPV continues until the final vortex breakdown event, which occurs every year sometime between mid-November and mid-January. The year of 2002 is a notable exception to this description as it was associated with the only documented SSW in the SH during the observational record; in 2002 the downward progression of the SSPV was substantially accelerated relative to its usual behaviour (e.g., Hio and Yoden 2005). Interannual variations in the SSPV lifecycle, such as those seen in 2002, were previously investigated by Kuroda and Kodera (1998) and Hio and Yoden (2005) by means of a multiple empirical orthogonal function (EOF) analysis on zonal-mean zonal wind. We employ a similar method using polar cap averaged geopotential height at 30hPa. The use of polar cap averaged geopotential height allows us to relate our results more directly to the Annular Mode indices that are considered later in the paper.

Figure 3a shows the seasonal evolution of polar cap averaged geopotential height at 30hPa. It is plotted from March through until February as the vortex occasionally persists into January in the lower regions of the stratosphere. Interannual variability is seen to be largest from August until

¹Inspection of individual years reveals that the downward progression occurs concurrently with transient vacillations in the magnitude of $[u]$, which are associated with the development of eastward-travelling anticyclones about the polar vortex (e.g., Hio and Yoden 2004, and references therein). As the present paper is exclusively concerned with an analysis of the zonal-mean circulation, we do not document this three-dimensional behaviour further.

January. The exceptional year of 2002 is also plotted for comparison. To perform a multiple EOF analysis on our 38 year dataset we proceed by combining 12 months of data (starting from March) in a vector $\mathbf{x}^i$ as

$$\mathbf{x}^i = [Z^i(1), \dots, Z^i(12)]^T \quad (1)$$

where $Z^i(m)$ is the anomalous monthly averaged polar cap averaged geopotential height at 30hPa for the m th month of the i th year. The leading modes of variability are then extracted as the eigenvectors of the covariance matrix calculated from $\mathbf{x}^i$. The leading mode (EOF1) is shown in Figure 3b. This leading mode explains over 73% of the total variance and is clearly separated from the second EOF (North et al. 1982). Its monopolar structure suggests that for a year where a strong or weak SSPV develops in winter (negative or positive polar cap average geopotential height anomalies respectively), it will tend to persist for the remainder of the SSPV lifecycle until the vortex breakdown event in summer (see also Gerber et al. 2010). The principal component (PC1) time series of EOF1 is shown in Figure 4. Weak (W) SSPV years are associated with a positive PC1 value and strong (S) SSPV years are associated with a negative value. Inspection of this plot reveals that the extreme values of PC1 (defined as the upper and lower quartiles of the data) are distributed in a somewhat specific manner. In particular, the extreme values are clustered in the second half of the dataset, and there is a tendency for extreme positive years to directly follow extreme negative years. We have made an attempt at quantifying the significance of these features in the Appendix ($p \sim 0.02$ and $p \sim 0.06$ respectively); we discuss potential explanations in section 5.

To explore how the EOF picture of interannual variability relates to the long-term average behaviour described earlier, we follow Hio and Yoden (2005) and perform a composite analysis on zonal-mean zonal wind using the W and S years of our PC1 index. We do this by forming monthly averages of $[u]$ for W and S years separately and then calculating the difference between them.

166 The results are presented in Figure 5. The principal difference between the composites is that the
 167 entire downward progression of the SSPV is delayed in S years compared to W years. This delay
 168 results in a later average stratospheric vortex breakdown date in S years (16 December versus 30
 169 November). It has been suggested that the dynamics of late breakdown events differ from those
 170 of early breakdown events (e.g., Sun et al. 2014; Byrne et al. 2017) and this may explain the dif-
 171 ferences in January. A more modest difference between the composites is that the SSPV appears
 172 stronger in S years (as measured by inspection of the meridional gradients of $[u]$ on the equator-
 173 ward flank of the SSPV). This difference in strength is beyond that which can be accounted for by
 174 a simple translation in time between the composites. The most noticeable impact of this difference
 175 in strength is on the tilting of the SSPV during October. This can be seen more clearly in Figure 6,
 176 where monthly-average plots for W and S years are shown separately. During October, the SSPV
 177 undergoes a relatively rapid weakening and tilting of the winds in W years, whereas it is more
 178 resilient to this weakening and tilting in S years. S years are also associated with an extension
 179 of the strongest winds of the SSPV into the upper troposphere. This extension into the upper tro-
 180 posphere gives the appearance of something of a merger between the SSPV and the tropospheric
 181 EDJ; we return to the tropospheric impacts in more detail in section 4. Overall, it would appear
 182 that interannual variations between August and February can be largely described as a phase delay
 183 of the SSPV lifecycle in S years, with changes to the amplitude of the lifecycle (SSPV strength) a
 184 non-negligible secondary effect.

185 *b. Seasonal Persistence of SSPV Anomalies*

186 The results of the previous section suggest that perturbations to the SSPV during winter can per-
 187 sist until the vortex breakdown event in summer. To investigate this potential predictive capability
 188 of the SSPV we employ a procedure suggested by Fioletov and Shepherd (2003) for total column

189 ozone and compute correlation coefficients between a measure of the SSPV at a given month of
190 the year and at subsequent months (see Figure 7). We use polar cap averaged geopotential height
191 at 30hPa as our SSPV measure and we remove the year of 2002 from this correlation analysis due
192 to its outlier nature. Furthermore, we also linearly detrend all our data prior to analysis as the
193 Southern Hemisphere stratosphere has been influenced by a well-documented trend in ozone (see
194 Thompson et al. 2011, and references therein). This influence is most clearly visible in a long-term
195 trend for the breakdown date of the SSPV (see Byrne et al. 2017, and references therein).

196 Inspection of Figure 7 suggests that SSPV predictability is considerable, particularly between
197 the months of September and January. Predictability is seen to develop from August, with the
198 longest period of predictability emerging around October, consistent with the peak of EOF1 in
199 Figure 3b. Correlation values above 0.6 are found for November, December and January based on
200 knowledge of the state of the SSPV in October. Predictability then decays following this October
201 peak. These results are consistent with an hypothesis that perturbations to the SSPV in winter can
202 lead to a shift in the statistics of the vortex breakdown event in the following summer. We have also
203 made a separate attempt at quantifying this statement by constructing a linear predictor model for
204 the SSPV breakdown date for each year based on monthly-mean polar cap averaged geopotential
205 height at 30hPa (Figure 8). A statistically significant relationship is seen to exist between these
206 two quantities from August, providing further evidence that perturbations to the SSPV in winter
207 can lead to a shift in the statistics of the vortex breakdown event in the following summer.

208 Another means of exploring the association between perturbations to the SSPV lifecycle and the
209 vortex breakdown date involves the use of a graphical method previously suggested by Hirano et al.
210 (2016), building on the ‘abacus plots’ of Hitchcock et al. (2013). Polar cap averaged geopotential
211 height anomalies at 30hPa are computed for each day between September 1 and February 1, and are
212 used to construct yearly time series. The yearly time series are then arranged chronologically by

breakdown date. The result is plotted in Figure 9. To a first approximation the figure is seen to be in reasonable agreement with the previous analysis: the latest breakdown dates are associated with a strong SSPV in the preceding months, while the opposite is found for the earliest breakdown dates. Closer inspection suggests two further features of interest. Firstly, evidence of a strong SSPV is often seen to emerge at 30 hPa by September 1, and this behaviour would appear to largely persist until the vortex breakdown event in summer; in contrast, evidence of a weakened SSPV is occasionally not seen to emerge until late September. It may be the case that some weak SSPV years are more clearly understood in terms of a single dynamical event (e.g., 1982; see Newman 1986). This may be suggestive of a fundamental asymmetry between weak and strong vortex years, perhaps related to the inherently dynamical nature of weak vortex years, with subsequent implications for the predictability timescale of the vortex breakdown event in weak SSPV years. However, confirmation of this statement is likely to be outside the scope of what is possible based on re-analyses.

The second feature that emerges from inspection of Figure 9 is that occasionally years with a weak SSPV are associated with a somewhat delayed vortex breakdown date, with opposite behaviour for years with a strong SSPV. From inspection of the particular examples for weak SSPV events, it appears that years with a large vortex weakening can occasionally be associated with a brief recovery of the vortex in late spring. The years of 2007 and 2014 are the outstanding examples of this behaviour. From inspection of the particular examples for strong SSPV events, it appears that as the SSPV nears the end of its lifecycle it can occasionally break down rather dramatically. The years of 1980 and 1997 are the outstanding examples of this behaviour. While these exceptional years are not sufficient to affect the qualitative conclusions of our analysis, they may be of interest for seasonal forecasting applications, where a quantitative assessment is more important. Figure 9 suggests that forecasts which have been initialised sometime in early Novem-

ber may be able to capture the breakdown behaviour in these years. It should be noted that the potential benefits of forecasts initialised in November need not be restricted to the short-medium range, as the timing of the breakdown event represents a leading-order influence on large-scale circulation variability during November, December and even January (Sun et al. 2014; Byrne et al. 2017, see Figure 1).

Before concluding this section we also consider the role of the QBO, as previous research has suggested a potential for the QBO to perturb the SSPV lifecycle during winter (e.g., Baldwin and Dunkerton 1998; Anstey and Shepherd 2014). We proceed by repeating our composite analysis from the previous section using July monthly-mean winds at 20hPa to define the phase of the QBO (Anstey and Shepherd 2014, see Table 1); we again remove the year 2002 from our analysis due to its outlier nature. The results of our analysis are shown in Figure 10. Based on inspection of the individual months of this figure it would appear that there is indeed an association between perturbations to the SSPV lifecycle and the phase of the QBO, with weak SSPV years associated with an easterly winter QBO and strong SSPV years associated with a westerly winter QBO. As an alternative measure of this association we also test whether there is evidence of a statistical relationship between our PC1 index from Section 3 and the phase of the QBO (see the Appendix). The results are suggestive of an association ($p \sim 0.06$), although our sample size again limits the statistical power of our analysis. Thus it would appear likely that there is an association between the phase of the QBO and perturbations to the SSPV lifecycle, although the strength of this association is not so large that it can be clearly detected in small sample sizes.

4. Stratosphere-Troposphere Coupling

a. Interannual Variations

The results of the previous section suggest that there is the potential for skilful seasonal forecasting in the SH stratosphere between August and February at least. As was highlighted in the references in the Introduction, stratosphere-troposphere coupling in the SH has been regularly documented for this time of year. Thus we now consider whether there is also evidence for the potential for skilful seasonal forecasting in the troposphere, based on knowledge of the initial stratospheric state. We begin by describing the long-term behaviour of the tropospheric EDJ using two separate measures. For our first measure we use vertically averaged zonal-mean zonal wind between 1000 and 250 hPa, denoted $\langle [u] \rangle$ (Byrne et al. 2017). For our second measure we use the difference in zonal-mean sea level pressure between 50 and 65 S, denoted ZI (Bracegirdle 2011); this difference in sea level pressure can be viewed as the SH equivalent to the NH zonal index (Kidson 1988). Long-term averages for both of these measures are shown in Figure 11 and Figure 12a. Inspection of these figures reveals a clear semi-annual oscillation in the location of the EDJ, with the strongest winds closest to the pole in late March and October. As the present paper is concerned primarily with coupled stratosphere-troposphere behaviour from late winter, we now restrict our attention to describing EDJ behaviour between August and February.

From August until late September the long-term average location of the EDJ undergoes little change. Starting from about late September, the EDJ transitions poleward until early November. This poleward transition of the EDJ is also associated with an intensification of the winds. Inspection of individual years suggests that this picture of a more poleward and intense EDJ in October is a reasonable description, although the intensification of the winds is more pronounced in some years than in others. The years of 1988 and 2002 are two clear exceptions to this description (not

shown), both having very clearly defined equatorward jets. These years are also notable as having the two largest values in our PC1 index of stratospheric variability (Figure 4). Large stratospheric variations during these years were associated with a vigorous minor warming (Hirota et al. 1990) and an SSW event respectively. From about mid-November onwards the EDJ undergoes an equatorward transition. This equatorward transition has been the focus of a previous study (Byrne et al. 2017) and we refer the reader to that paper for more details. Broadly speaking, it reflects a shift in latitude of the EDJ in association with the vortex breakdown in the stratosphere.

To investigate the potential for interannual variations in the stratosphere to impact the troposphere, we begin by revisiting Figure 5. In the troposphere, statistically significant differences between W and S years are present from September through January, consistent with the earlier results of Hio and Yoden (2005). To examine these differences in greater detail, we have computed long-term averages of $\langle [u] \rangle$ and ZI for W and S years separately (Figure 12b and Figure 13). We begin by discussing the September and October differences. In both W and S years a poleward transition and intensification of the winds is seen from about late September, consistent with the long-term average behaviour in Figure 11. However, in S years this intensification and shift of the winds is of larger amplitude. This is particularly clear during October, where changes in ZI are found to be dominated by a reduction in zonally-averaged sea level pressure at 65 S (not shown), consistent with a more poleward and intense EDJ in S years. This enhanced poleward shift of the EDJ during S years is associated with a stronger and deeper SSPV in the stratosphere (see previous section). Thus, while the SSPV lifecycle is accelerated in W years on average, it is also weaker and smaller in size, and it is the combination of these features that apparently explains why an approximate phase delay in the SSPV lifecycle in S years emerges as an approximate change in amplitude (i.e, a poleward transition and intensification) in the EDJ lifecycle in the troposphere during October.

Between November and early February the difference in tropospheric statistics can be largely understood in terms of the results of Byrne et al. (2017). Broadly speaking, it reflects a difference in the timing of the summer equatorward transition of the EDJ, which is closely tied to the vortex breakdown event in the stratosphere. The latter is related to the winter strength of the SSPV (see previous section). As a result, S years are on average expected to have a delayed, and somewhat reduced, equatorward transition of the EDJ compared to W years. Thus it would appear that the difference in tropospheric statistics between September and February can be approximately described as a combination of a change in amplitude (September/October/January) and a phase delay (November until January) of the EDJ lifecycle, and that these differences are closely tied to the state of the SSPV in the stratosphere.

b. Alternative Circulation Perspective

The results of the previous section suggest at least two components to skilful seasonal forecasting in the SH troposphere during spring and summer. The first component represents a change in the September/October EDJ statistics in association with the apparent downward merger of the SSPV and the EDJ. The second component represents a change in the November - February EDJ statistics in association with the timing and type of stratospheric vortex breakdown event. Based on our analysis in Section 3, this would suggest that skilful seasonal forecasts of the troposphere might be possible based on knowledge of the state of the winter SSPV. To test this hypothesis, we repeat a similar analysis from section 3 and compute correlation coefficients between a measure of the SSPV at a given month of the year and a measure of the troposphere at subsequent months. We use polar cap averaged geopotential height at 30hPa and the ZI time series as our respective measures. The results of this calculation for August - December are presented in Figure 14a. Statistically significant correlations are seen to emerge for predictions of the troposphere

327 from October until January. Furthermore, when this calculation is repeated using the troposphere
328 as a predictor of itself (Figure 14b) the correlations are seen to largely vanish. This is consistent
329 with previous work by Gerber et al. (2010) who used an Annular Mode index to highlight that at
330 this time of the year the stratosphere is a better predictor of the troposphere than is the troposphere
331 itself.

332 As an alternative measure of the potential for skilful seasonal forecasting in the SH troposphere
333 we provide an update of the Annular Mode ‘dripping paint’ plots (Thompson et al. 2005, Fig-
334 ure 15a and Figure 15b). Although the Annular Modes are usually defined via an EOF analysis,
335 the leading principal component time series is closely related to polar cap averaged geopotential
336 height (Baldwin and Thompson 2009). As such, much of the behaviour in Figure 15a and Figure
337 15b can be interpreted using the analysis from earlier sections. Inspection of these figures reveals
338 a coherent descent of circulation anomalies in the stratosphere, with weak vortex years associ-
339 ated with persistent positive anomalies and with the opposite behaviour for strong vortex years.
340 This behaviour is consistent with a phase delay in the shift-down of the SSPV between W and S
341 years (see Section 3). Furthermore, both weak and strong vortex years are seen to exhibit substan-
342 tial intraseasonal coherence in the troposphere, consistent with coupled variability between the
343 stratosphere and troposphere (see previous subsection), and supporting the claim of a concomitant
344 potential for skilful seasonal forecasting in the troposphere.

345 The intraseasonal coherence of anomalies in the troposphere and stratosphere suggests that (An-
346 nular Mode) anomalies have a strong synchronisation with the seasonal cycle during this time of
347 year. As a check of this statement, we have computed a plot of weak and strong vortex years as a
348 function of calendar day of the year (Figure 15c and Figure 15d). The anomalies in these calendar
349 year plots are seen to be of a similar magnitude and pattern as those in the previous ‘lag’ plots. This
350 suggests that the timescale separation implicitly assumed in a description of circulation variabil-

ity as (stationary stochastic) anomalies about a slowly-varying seasonal cycle is not well satisfied during this time of year. In particular, the long intraseasonal persistence of the anomalies suggests that variations are more naturally viewed as shifts in the seasonal cycle rather than as anomalies about a seasonal cycle. Thus, combining the results from this and previous sections of the paper, we are led to propose an alternative perspective for circulation variability between September and February. We argue that during this time of year, variability of the large-scale extra-tropical tropospheric and stratospheric circulations is most naturally viewed as a shift in the seasonal cycle of a single, coupled entity and that the statistics of this variability can be determined by conditioning on the stratospheric circulation from the preceding winter. We note the close similarity between this perspective and those proposed by Kuroda and Kodera (1998) and Hio and Yoden (2005) using earlier versions of re-analysis products.

5. Summary and Discussion

We have considered the statistical predictability of the SH stratospheric polar vortex breakdown event, using re-analysis data. We have focused on the time period from August until February, which is associated with the shift-down of the SSPV from its midwinter position. We have also considered coupled variations between the troposphere and stratosphere during this time. Our results can be broken down into three different components.

Firstly, we have presented evidence for statistical predictability of the stratospheric polar vortex breakdown event arising from persistent variations of the SSPV in the preceding winter and spring. Evidence of statistical predictability is found from August, with maximum predictability emerging around October. This memory of (stratospheric) initial conditions over the course of several months is notable as being significantly longer than timescales that have previously been associated with atmospheric initial condition skill (Kirtman and Pirani 2007). A relationship between

374 perturbations to the winter SSPV and the phase of the midwinter QBO has also been documented,
375 consistent with previous results (Anstey and Shepherd 2014, and references therein). This rela-
376 tionship, along with a similar relationship between ENSO and the SSPV (see Byrne et al. 2017),
377 may represent an important source of interannual variability for the SSPV.

378 A separate potential source of interannual variability for the SSPV has been suggested by the
379 distribution of extreme years of our PC1 index (Figure 4). Extreme weak years of the SSPV
380 are found to have a tendency to directly follow extreme strong years ($p \sim 0.06$; see Appendix),
381 suggesting that memory of the SSPV can occasionally persist from one year to the next. This
382 is reminiscent of an earlier model result of Scott and Haynes (1998). In addition, extreme years
383 of our PC1 index, of both signs, are found to be clustered in the second half of our dataset (p
384 ~ 0.02 ; see Appendix). Ozone depletion has led to a delay in the SSPV breakdown through
385 the satellite record, which on its own would increase the number of negative values. However
386 there is also a large number of positive values. It may be the case that a feedback between ozone
387 and SSPV dynamics has increased the likelihood of extreme SSPV events during this period. A
388 similar remark has previously been made in Black and McDaniel (2007), where the authors noted
389 an apparent increase in interannual variability of the SSPV during later years of the satellite era.

390 The second component to our results builds on previous work by Kuroda and Kodera (1998)
391 and Hio and Yoden (2005), who documented coupled variability between the stratosphere and tro-
392 posphere during austral spring and early summer. We have presented evidence for the statistical
393 predictability of variations in the troposphere during this time, based on knowledge of the strato-
394 spheric initial state; moreover, this predictability is seen to largely vanish when the troposphere
395 is used as a predictor of itself (see also Gerber et al. 2010). The physical explanation for this
396 tropospheric skill can be traced to seasonal shifts in latitude of the EDJ: strong SSPV years are

397 associated with an enhanced poleward transition in September/October and a delayed equatorward
398 transition between November and January, with opposite behaviour in weak SSPV years.

399 Related to this, recent research has provided evidence of model skill in forecasting the poleward
400 transition of the EDJ, based on a model initialisation in early August (Seviour et al. 2014). The
401 present work suggests that such skill should also be realisable in forecasting the equatorward
402 transition of the EDJ, particularly for a model initialisation in early November. The use of a
403 similar diagnostic to that proposed by Newman (1986) may represent a helpful tool for assessing
404 model fidelity around the time of this equatorward transition. The original diagnostic of Newman
405 (1986) considered the difference between 30hPa zonal-mean temperature at 80 and 50 S. We find
406 that if this diagnostic is instead defined at the 125hPa level, the result is an almost identical time
407 series for the stratospheric vortex breakdown date as that considered in the present study. The
408 benefit of this alternative diagnostic is that it does not require that the SSPV breakdown event be
409 defined in terms of a single threshold value. While the threshold definition appears to work well
410 for the real atmosphere (Black and McDaniel 2007; Byrne et al. 2017), it may be the case that it is
411 less suitable for a model with an unrealistic climatology.

412 There is evidence that the benefit of skilful forecasting of the equatorward transition of the EDJ
413 can be quite substantial (see Byrne et al. 2017, and Figure 1). As a very recent example, we
414 highlight the unprecedented retreat of Antarctic sea-ice during 2016 (Turner et al. 2017). Sea-ice
415 decrease during this season was closely linked to high-latitude circulation anomalies; in particular,
416 the November SAM was notable for assuming its most negative value during the satellite era. Such
417 a large negative value appears to have been closely associated with the equatorward transition of
418 the EDJ, which was one of the earliest during the satellite era (see Table 1). Thus, the weak
419 SSPV of 2016 and the exceptionally early transition of the EDJ may offer a partial explanation
420 to the puzzling behaviour of sea-ice during that year (Turner and Comiso 2017). Furthermore,

421 it implicates the stratosphere as a potentially important source of low-frequency variability in
422 variations of Antarctic sea-ice extent.

423 The poleward and equatorward transition of the EDJ in spring and summer is part of a broader
424 semi-annual oscillation of the EDJ (van Loon 1967). The SAO has previously been interpreted as
425 a largely baroclinic phenomenon, emerging as a result of contrasting seasonal evolutions of sur-
426 face temperature over the Southern Ocean and the Antarctic regions (see also Karoly and Vincent
427 1998). Our work emphasises the additional role of the stratosphere in a complete theory for the
428 SAO, at least between September and February. Such a role for the stratosphere has previously
429 been considered by Bracegirdle (2011). We further note that the impact of stratospheric ozone de-
430 pletion offers a natural explanation for the documented modulation of the SAO during the second
431 half of the year since the 1970's (Hurrell and van Loon 1994). In light of recent research that has
432 implicated stratospheric circulation changes in long-term EDJ changes in May (Ivy et al. 2017),
433 it may also be of interest to explore the potential role of the stratosphere in EDJ behaviour during
434 the first half of the calendar year.

435 The third and final component to our results again builds on previous work by Kuroda and
436 Kodera (1998) and Hio and Yoden (2005). Based on our earlier results, we have proposed an
437 alternative perspective for large-scale SH extra-tropical circulation variability between September
438 and February. We argue that during this time of year, variability is most naturally viewed not as
439 anomalies about a climatology, but rather as a shift in the seasonal cycle of a single, coupled entity,
440 and that the statistics of this variability can be determined by conditioning on the stratospheric
441 circulation in the preceding winter. There are several examples where this perspective may shed
442 new light.

443 Firstly, this perspective suggests that long Annular Mode timescales during austral spring and
444 summer should not be interpreted as an increased persistence of perturbations to some slowly-

445 varying seasonal cycle. Rather, it suggests that they instead reflect a phase shift of the seasonal
446 cycle. An instructive example of the differences between these two statements can be found by
447 considering the increased persistence of Annular Mode timescales in the troposphere during aus-
448 tral summer (Gerber et al. 2010). From the perspective of perturbations to some slowly-varying
449 seasonal cycle, this increased persistence has been argued to arise from eddy feedbacks in the tro-
450 posphere (e.g., Kidston et al. 2015). In our proposed perspective, the increased persistence reflects
451 year-to-year variability in the phase of the seasonal cycle (i.e., in the equatorward transition of the
452 jet); it is not necessarily evidence of an eddy feedback in the troposphere (see Byrne et al. (2017)
453 for further discussion). Note that the lag correlation between the SAM and eddy momentum flux
454 convergence cannot be interpreted as evidence in favour of an eddy feedback (Byrne et al. 2016).

455 A second example of the insight offered by this perspective relates to the results of Byrne et al.
456 (2016). In that study it was noted that SAM anomalies (along with the associated eddy momen-
457 tum flux anomalies) persisted for longer during austral spring and early summer than in any other
458 season. The present perspective offers a natural explanation for this increased persistence of cir-
459 culation anomalies. Furthermore, it also suggests an hypothesis for the quasi-two year peak of
460 the SAM that was noted in Byrne et al. (2016): perturbations to the SSPV lifecycle during win-
461 ter emerge as persistent anomalies in the tropospheric circulation every year between September
462 and February, resulting in a pronounced harmonic of the annual cycle in the SAM index. Low-
463 frequency perturbations to the SSPV (such as the QBO or ENSO) can then excite these harmonics,
464 with the quasi-two year peak being the highest-frequency such harmonic. It is left to future work
465 to establish the validity of this hypothesis.

466 We conclude by noting that the perspective of circulation variability originally proposed by
467 Kuroda and Kodera (1998) and Hio and Yoden (2005) also considered the early and midwinter
468 months of the year. These months have not been considered in the present work. Thus it may be the

case that the perspective on circulation variability proposed in this paper can also be extended to other months of the year. In this respect, the month of July looks most promising (see also Kuroda and Kodera (1998) for a more detailed discussion). In the stratosphere, July is notable as the time of year where the SSPV undergoes its annual poleward shift from subtropical to polar latitudes (e.g., Shiotani et al. 1993). In the troposphere, July is notable for large interannual variability in the location of the EDJ (e.g., Trenberth 1984). It would be of interest to determine the extent of the relationship between these two quantities; however, it should be noted that as a result of the low-latitude position of the SSPV during much of July, Annular Mode (i.e., polar cap) diagnostics may not be the optimum measure of circulation variability for this time of year. We also draw attention to the theoretical work of Scott and Haynes (2000, 2002) which suggests that the late winter configuration of the SSPV (i.e., the emergence of W or S years) can often be traced back to the early winter wave forcing (see also Shiotani et al. (1993) for some observational support of this statement). The year of 2002 would appear to be a particular example of such a scenario (Harnik et al. 2005).

Acknowledgments. This article is based on Chapter 4 of the PhD thesis of the first author (Byrne 2017). We are grateful to Tim Woollings for many helpful discussions and suggestions in the preparation of this material. We thank Alan Plumb, Steven Hardiman, Andrew Charlton-Perez and Tom Frame for helpful discussions and feedback. We also thank Andrew Charlton-Perez and Dave Thompson for suggesting the calculation of Figure 8. Funding support is acknowledged from the European Union's F7 research and innovation program under the Marie Skłodowska-Curie Grant Agreement 654492 and from European Research Council Advanced Grant 'Understanding the Atmospheric Circulation Response to Climate Change' (ACRCC), Project 339390. We thank the European Centre for Medium-Range Weather Forecasts for the ERA-Interim data.

APPENDIX

To quantify whether extreme values of our PC1 index are clustered in the second half of our dataset we proceed as follows. First we generate a synthetic time series of eighteen ‘0s’ and twenty ‘1s’. These ‘0s’ and ‘1s’ are randomly distributed within the time series and are intended to mimic extreme events in our original PC1 index (which contains 20 extreme events). Next we calculate the difference between the sum of the first 19 elements and the remaining 19 elements of this synthetic time series to arrive at a value d . Finally we repeat this calculation 10^6 times to form a distribution for d . The difference for our PC1 time series is $d = 8$. According to our synthetic distribution, the probability of $|d| \geq 8$ is $p \sim 0.02$.

To quantify whether extreme positive values of our PC1 index have a tendency to follow extreme negative years we proceed as follows. First we generate a synthetic time series of ten ‘-1s’ and ten ‘+1s’. These ‘-1s’ and ‘+1s’ are randomly distributed within a time series of length 38, padded with zeros, and are intended to mimic extreme negative and extreme positive events in our original PC1 index. Next we derive a new time series by forming the difference between adjacent entries in our original synthetic time series. For example, if the first and second entries of our synthetic time series are -1 and +1 respectively, the first entry of our derived time series will be +2. Once we have constructed our derived time series, we count the number of occurrences of ‘+2’ in this time series – ‘+2’ is a unique identifier of an extreme positive event directly following an extreme negative event. Finally we repeat this calculation 10^6 times to form a distribution. The number of ‘+2s’ in our PC1 time series is 5. According to our synthetic distribution, this has an approximate p-value of $p \sim 0.06$.

To determine whether there is a statistical relationship between the phase of the QBO and our PC1 index, we first note that 15 easterly QBO years have been associated with positive PC1 years

515 and 6 easterly QBO years have been associated with negative PC1 years (by symmetry this cal-
516 culation will be the same for westerly QBO years). We then test the statistical significance of this
517 configuration using a hypergeometric sampling distribution, with the result being an approximate
518 p-value of 0.06.

LIST OF TABLES

Table 1.	Classification of 38 yr based on PC1 (Fig. 4) along with classifications for the QBO and the breakdown date of the SSPV. For PC1, W is a weak SSPV year and S is a strong SSPV year. For the QBO, E represents easterly monthly-mean zonal wind values for July at 20hPa and W represents westerly values. The brackets denote actual monthly-mean values according to the ERA-Interim re-analysis product. For the SSPV breakdown date (BD; Byrne et al. 2017) E represents extreme early years, L represents extreme late years, e represents years before the median breakdown date and l represents years after the median breakdown date. Breakdown dates for each year are shown in brackets.	32

672	LIST OF FIGURES	
673	Fig. 1.	Correlation values between DJF 500 hPa geopotential height anomalies and the date of the
674		stratospheric vortex breakdown during the satellite era. All data has been linearly de-trended
675		prior to calculation of correlation values. Stippled regions represent correlation values that
676		are statistically significant at the 5% level, based on a two-sided test of the Student's t statis-
677		tic. Correlation values between -0.2 and 0.2 are colored white for presentation purposes.
678		35
679	Fig. 2.	Monthly-mean climatologies of [u]. 36
680	Fig. 3.	(a) Seasonal cycle of polar cap averaged geopotential height at 30 hPa (thick black line).
681		Shading represents +/- 2 standard deviation interval for each day of the year. Dashed line
682		represents daily values during the year 2002. (b) EOF1 from multiple EOF analysis on polar
683		cap averaged geopotential height at 30hPa (see text). EOF is plotted in m and represents
684		anomaly associated with 1 standard deviation of principal component time series. 37
685	Fig. 4.	Principal component time series of EOF1. The 10 largest positive (red dots) and negative
686		(blue dots) years are also plotted, along with the threshold values for these extreme years
687		(dashed lines). 38
688	Fig. 5.	Monthly-mean differences in [u] between S and W years (shading). Black contours repre-
689		sent regions where differences are statistically significant at the 5 % level, based on a one-
690		sided two-sample Student's t test. Note the non-linear colour scale required for including
691		tropospheric and stratospheric differences in the same figure. 39
692	Fig. 6.	Monthly-mean [u] for S and W years. 40
693	Fig. 7.	Correlation coefficients between polar cap averaged 30 hPa geopotential height at a given
694		month of the year with values in the subsequent months. For example, the correlation coef-
695		ficient between polar cap averaged geopotential height in March and in the subsequent April
696		is shown in the first column for March. Data has been linearly de-trended for each month
697		prior to calculation. Cells that are not shaded grey represent values that are statistically sig-
698		nificant at the approximate 5 % level based on a one-sided test of Student's t statistic. 2002
699		is not included in the correlation analysis (see text). 41
700	Fig. 8.	Variations in the date of the stratospheric vortex breakdown regressed against monthly-mean
701		polar cap averaged geopotential height at 30hPa for a) August, b) September, c) October and
702		d) November. All data has been linearly de-trended prior to calculation. Correlation values
703		for each month are located in the top right hand corner of each plot. All correlation values are
704		statistically significant at the 5% level, based on a one-sided test of the Student's t statistic.
705		2002 is not included in the correlation analysis (see text). 42
706	Fig. 9.	Yearly time series of polar cap averaged geopotential height anomalies at 30hPa. Positive
707		anomalies are red and negative anomalies are blue. Units are m. For reference, the anomaly
708		on November 1 1988 is approximately + 700 m. The shaded region indicates the suggested
709		period for re-initialisation of a forecast model (see text). The black line indicates the strato-
710		spheric vortex breakdown date for each year. 2002 is plotted separately to other years (see
711		text). 43
712	Fig. 10.	Monthly-mean differences in [u] between westerly and easterly QBO phase (shading). 2002
713		is not included in the analysis (see text). Black contours represent regions where differences
714		are statistically significant at the 5 % level, based on a one-sided two-sample Student's t

715	test. Note the non-linear colour scale required for including tropospheric and stratospheric	
716	differences in the same figure.	44
717	Fig. 11. Climatology of $\langle [u] \rangle$ (shading) and jet-latitude index (white line). Units of $\langle [u] \rangle$ are m s^{-1} .	45
718		
719	Fig. 12. (a) Climatology of monthly-mean difference in zonally-averaged sea level pressure between	
720	50 and 65 S. (b) Similar calculation for W years (red line) and S years (blue line). Shading	
721	represents ± 1.96 standard error interval for each set of years.	46
722	Fig. 13. (a) Climatology of $\langle [u] \rangle$ (shading) and jet-latitude index (white line) for S years between	
723	August 1 and February 1. (b) Similar calculation for W years. Jet-latitude index climatolo-	
724	gies have also been smoothed using a moving-average filter for presentation purposes. Units	
725	of $\langle [u] \rangle$ are m s^{-1}	47
726	Fig. 14. (a) Correlation coefficients between polar cap averaged 30 hPa geopotential height at a given	
727	month of the year with ZI in the subsequent months. (b) Correlation coefficients between	
728	ZI at a given month of the year with ZI in the subsequent months. Data has been linearly	
729	de-trended for each month prior to calculation in both figures. Cells that are not shaded grey	
730	represent values that are statistically significant at the 5 % level based on a one-sided test of	
731	Student's t statistic. 2002 is not included in the correlation analysis (see text).	48
732	Fig. 15. (a, b) Composite plots of Annular Mode indices for the 13 weakest and 13 strongest SSPV	
733	years. Weak and strong years are defined using the Annular Mode index at 30 hPa. Dashed	
734	vertical line represents onset date (see text). Shading interval is 0.25 standard deviations and	
735	contour interval is 0.5 standard deviations. Shading is drawn for values greater than ± 0.25	
736	standard deviations. (c, d) Similar calculation but for calendar day of the year.	49

500hPa Geopotential Height (DJF 1979 - 2016)

FIG. 1. Correlation values between DJF 500 hPa geopotential height anomalies and the date of the strato-
spheric vortex breakdown during the satellite era. All data has been linearly de-trended prior to calculation of
correlation values. Stippled regions represent correlation values that are statistically significant at the 5% level,
based on a two-sided test of the Student's t statistic. Correlation values between -0.2 and 0.2 are colored white
for presentation purposes.

FIG. 2. Monthly-mean climatologies of $[u]$.

30hPa Polar Cap Geopotential Height

FIG. 3. (a) Seasonal cycle of polar cap averaged geopotential height at 30 hPa (thick black line). Shading represents ± 2 standard deviation interval for each day of the year. Dashed line represents daily values during the year 2002. (b) EOF1 from multiple EOF analysis on polar cap averaged geopotential height at 30hPa (see text). EOF is plotted in m and represents anomaly associated with 1 standard deviation of principal component time series.

FIG. 4. Principal component time series of EOF1. The 10 largest positive (red dots) and negative (blue dots) years are also plotted, along with the threshold values for these extreme years (dashed lines).

749 FIG. 5. Monthly-mean differences in $[u]$ between S and W years (shading). Black contours represent regions
 750 where differences are statistically significant at the 5 % level, based on a one-sided two-sample Student's t test.
 751 Note the non-linear colour scale required for including tropospheric and stratospheric differences in the same
 752 figure.

FIG. 6. Monthly-mean $[u]$ for S and W years.

FIG. 7. Correlation coefficients between polar cap averaged 30 hPa geopotential height at a given month of the year with values in the subsequent months. For example, the correlation coefficient between polar cap averaged geopotential height in March and in the subsequent April is shown in the first column for March. Data has been linearly de-trended for each month prior to calculation. Cells that are not shaded grey represent values that are statistically significant at the approximate 5 % level based on a one-sided test of Student's t statistic. 2002 is not included in the correlation analysis (see text).

FIG. 8. Variations in the date of the stratospheric vortex breakdown regressed against monthly-mean polar cap averaged geopotential height at 30hPa for a) August, b) September, c) October and d) November. All data has been linearly de-trended prior to calculation. Correlation values for each month are located in the top right hand corner of each plot. All correlation values are statistically significant at the 5% level, based on a one-sided test of the Student's t statistic. 2002 is not included in the correlation analysis (see text).

FIG. 9. Yearly time series of polar cap averaged geopotential height anomalies at 30hPa. Positive anomalies are red and negative anomalies are blue. Units are m. For reference, the anomaly on November 1 1988 is approximately + 700 m. The shaded region indicates the suggested period for re-initialisation of a forecast model (see text). The black line indicates the stratospheric vortex breakdown date for each year. 2002 is plotted separately to other years (see text).

FIG. 10. Monthly-mean differences in $[u]$ between westerly and easterly QBO phase (shading). 2002 is not included in the analysis (see text). Black contours represent regions where differences are statistically significant at the 5 % level, based on a one-sided two-sample Student's t test. Note the non-linear colour scale required for including tropospheric and stratospheric differences in the same figure.

FIG. 11. Climatology of $\langle [u] \rangle$ (shading) and jet-latitude index (white line). Units of $\langle [u] \rangle$ are m s^{-1} .

FIG. 12. (a) Climatology of monthly-mean difference in zonally-averaged sea level pressure between 50 and 65 S. (b) Similar calculation for W years (red line) and S years (blue line). Shading represents ± 1.96 standard error interval for each set of years.

FIG. 13. (a) Climatology of $\langle [u] \rangle$ (shading) and jet-latitude index (white line) for S years between August 1 and February 1. (b) Similar calculation for W years. Jet-latitude index climatologies have also been smoothed using a moving-average filter for presentation purposes. Units of $\langle [u] \rangle$ are m s^{-1} .

FIG. 14. (a) Correlation coefficients between polar cap averaged 30 hPa geopotential height at a given month of the year with ZI in the subsequent months. (b) Correlation coefficients between ZI at a given month of the year with ZI in the subsequent months. Data has been linearly de-trended for each month prior to calculation in both figures. Cells that are not shaded grey represent values that are statistically significant at the 5 % level based on a one-sided test of Student's t statistic. 2002 is not included in the correlation analysis (see text).

784 FIG. 15. (a, b) Composite plots of Annular Mode indices for the 13 weakest and 13 strongest SSPV years.
 785 Weak and strong years are defined using the Annular Mode index at 30 hPa. Dashed vertical line represents
 786 onset date (see text). Shading interval is 0.25 standard deviations and contour interval is 0.5 standard deviations.
 787 Shading is drawn for values greater than ± 0.25 standard deviations. (c, d) Similar calculation but for calendar
 788 day of the year.
